**Abstract** The recently found metal casting mould from Gaj Oławski (SW Poland) was designed for the production of socketed axes typical for later stages of the Bronze Age in Poland (ca. 1100–900 BC). This unique artefact is a half of a durable, two-piece wedge-shaped mould and measures 17.5 × 7.2 × 4.0 cm. The surface of the mould is covered copper oxides and carbonates, and the remnant of beeswax was found on its inner surface. The metal forming mould consists of cored dendrites of Cu-dominated (Cu >96.5 wt%, up to 2.2 wt% Sn) and Cu impoverished (Cu ~86.0 wt%, Sn ~9.4 wt%, some Sb, As and Ag) end compositions and volumetrically subordinate  $\alpha + \delta$  eutectoid. The “as cast” structure of the metal shows that the mould was never used for molten metal casting. Since this kind of moulds was used for mass casting of metal, the Gaj Oławski one was probably never used, and the beeswax is the remain of its coating. This is the first remain of the Bronze Age beeswax described in metallurgical context in Europe.

## Introduction

Beeswax, although considered to be commonly used in prehistory, is a rare find in archaeological contexts. The most analysed archaeological waxy samples come from cosmetic and medical products, embalming materials, seals, artistic items, candles, waxy coatings and rock paintings (e.g. Kimpe et al. 2002; Evershed and Dudd 2003; Regert et al. 2005; Ribechini et al. 2008; Charrié-Duhaut et al. 2009; Namdar et al. 2009; Baeten et al. 2010; Stacey 2011; Luo et al. 2012; David et al. 2013; Ménager et al. 2014; Rosina et al. 2014). Among them, only in one case beeswax remains were identified in metallurgical context and sampled from ceramic moulds, used in lost wax casting (Namdar et al. 2009). Beeswax remnants from prehistoric European locations are even more uncommon with only a few examples known to date (Heron et al. 1994; Frade et al. 2014). In this paper, we present the study of a unique find of a Bronze Age metal casting mould on which wax remains are preserved. The mould is a recently discovered one from Gaj Oławski in southwestern Poland (Fig. 1). The wax remnants are characterised in detail as well as phase and major element chemical composition of the mould. According to our knowledge, this is the first description of wax related to mould of the European Bronze Age as well as the first one showing both phase and bulk chemical composition of the mould.

Metal casting moulds are a fascinating group of artefacts that have been recorded in many parts of Bronze Age Europe and were designed mostly to produce only one type of artefact. Despite some examples of moulds for pins, spearhead,

swords hilts and sickles, most of metal moulds were used for axe production. Various forms of metal axes have received wide interpretation from multi-purpose tools to symbols of power of newly rising elites which make them important element in studies on social transformation and technical innovations in the copper and early Bronze Age Europe (e.g. Kienlin 2010, pp. 80–117 with further references therein).

According to an opinion that is common also in Polish literature, metal casting moulds, due to their low resistance to high temperatures, were used exclusively for making wax or lead models and not for producing bronze products themselves (e.g. recently Machajewski and Maciejewski 2006). Some experimental work done as early as in 1940s proved however that the metal moulds could have been used successfully in the production of bronze artefacts and when controlled in terms of temperatures, did not get broken in the course of casting (e.g. Drescher 1957, p. 58; Mohen 1978, p. 27; Wirth 2003, p. 65 and references therein). Use of metal moulds for metal casting has been proved by some experimental work done on French, German and British artefacts (Mohen 1978, p. 28; Fleury 1991, pp. 269–270). Mohen argues the direct casting of bronze in metal forms, when controlled in terms of temperatures, was relatively uncomplicated and very much probable during the Bronze Age. Massive bronze moulds after coating with charcoals and warming up did not get broken in the course of repeated casting (Mohen 1978, pp. 28–29). Drescher (1957) reports a high durability of such moulds: after casting over 50 socketed axes in a single mould, no traces of use have been observed. Similar experiments have been done for various types of axes and sickles. The moulds were warmed up to 150–200 °C and reached 600 °C after metal was cast into them. Such simple operation slowed down the cooling of moulds and allowed to avoid inner structural tensions while pouring metal containing 6–10 % of tin and

temperature ca. 1000 °C (Mohen 1978, p. 28). Recent experiments proved that bronze moulds heated to ca. 300 °C could have been successfully used in axe production; however, direct cast into a metal mould required an extremely short cast time (3 s), otherwise finished products would be incomplete in edge areas (Wirth 2003, XVI).

Metal casting moulds are very rare in most parts of Europe including Poland with only six found to date. Five of them occurred in western Poland and one was discovered recently in eastern Poland (E. Kłosińska, pers. com.), but that still does not make any deposition pattern as they are too few. Except from small concentrations in western France and England (comp. Hansen 1991, fig. 49), it seems not possible to identify any clear distribution pattern on the European level—single finds are known from the Netherlands, Spain, Czech Republic, Slovakia and Hungary (e.g. Cordier 1962; Mohen 1978; Fleury 1991, pp. 269–270; Armbruster 2000; Kuijpers 2008, p. 89; Kosařova 2009, p. 75), mostly dated to the late Bronze Age, although several middle Bronze Age moulds occur as well (Wirth 2003, p. 84).

In Poland, three moulds were bog deposits while for the other two, no information is available. The studied artefact, although a stray find, was discovered at a stream what suggests a similar original context. All the metal moulds from Poland, their contexts and possible interpretations have been recently studied (Baron et al. 2014). The chemical data on casting moulds from Poland are restricted to those of Sałat et al. (2006) who described casting mould from Rosko in western Poland, accompanying the axes deposit dated at 900–700 BC. The XRF analyses of two parts of the mould presented by Sałat et al. (2006) show significant differences (Cu 87.03 and 90.05 wt%, Sn 11.61 and 5.25 wt%, Sb 0.44 and 2.30 wt%, As 0.18 and 1.00 wt%, Pb 0.22 and 1.00 wt%, Ni 0.27 and 0.26 wt%, respectively). These differences may arise from polyphase composition of the metal and inhomogeneous distribution of phases, similar to that described by us. However, no data on microstructure and phase composition of that mould are given by Sałat et al. (2006).

### The mould

During an archaeological surface survey in 2012, which took place north of Oława—a town about 30 km south-east of Wrocław in southwestern Poland, one of the archaeologists was given a half of a metal casting mould. This was an illegal discovery done by non-professional archaeologist probably with the use of metal detector. According to information provided by the founder, the artefact was discovered north-west of Gaj Oławski (Fig. 1) village in the Oława District, at the eastern edge of a ravine of a small, nameless stream. The whole area is now relatively flat and wet with a number of small streams both of natural and artificial origin. No

archaeological location was previously recorded there. The surface prospection and pottery shards collecting done after the mould had been found proved Neolithic, late Bronze Age and Celtic horizons of the site use. The discussed artefact is a half of a casting mould designed for the production of socketed axes. This is an example of a durable, two-piece wedge-shaped mould. The surface is covered with a green patina and number of corrosion marks (Fig. 2) which have been recognised as copper oxide and carbonates (Baron et al. 2014). The mould measures  $17.5 \times 7.2 \times 4.0$  cm, while the axe was designed to be 15.6 cm long with a socket diameter of 3.5 cm and a maximum blade width of 4 cm (Fig. 3). The weight of the item was 629.3 g.

On the inner side, at the negative edge, four pegs were evident, which most likely fitted into four holes in the lost part of the mould. The pegs were used to join and stabilise both elements during the casting. On the outer side, two heavily corroded knobs of unknown function occur. Perhaps they helped with tying together both elements of the mould or were used to open the still hot mould after the item had been cast. Such a function is sometimes given to outer loops, which

**Fig. 2** Metal casting mould from Gaj Oławski in southwestern Poland. The numbers refer to sampling locations. On the right side, heavy corrosion marks and two small knobs are visible. Photo by Ł. Kapa

**Fig. 3** Metal casting mould from Gaj Oławski in southwestern Poland. Drawn by N. Lenkow

often occur on moulds found in western Europe (e.g. Cordier 1962, fig. 1; Armbruster 2000, p. 41).

The negative shows that the mould was used to produce socketed axes of the so-called “Lusatian type”, characterised by a loop and an oval socket in cross section. This type is the most common one of socketed axes occurring mostly in deposits and dated to 1100–900 BC known from Poland (Kuśnierz 1998, p. 25). They occur mostly in Lower Silesia (southwestern Poland), with some examples from West Pomerania and western Great Poland (west Poland). A few were also found in Brandenburgia, Bohemia and Lusatia (Kuśnierz 1998, p. 31).

## Analytical methods

A material macroscopically similar to the beeswax forms smooth, semi-glossy spot situated by the parallel ribs and contrasting with the oxidised mould's inner surface (Fig. 4). It was possible to collect only small amounts of it for the Fourier transform infrared spectroscopy (FTIR) and gas chromatography/mass spectrometry (GC/MS). The investigated residue was a black, soft paste with a characteristic wax-like gloss (the spot diameter was 3–4 mm). The sample was collected by a steel scalpel and weighted and 0.2 mg was mixed with 200 mg of spectral KBr (PIKE Technologies) in an agate mortar. The mixture of the sample and KBr was pressed (10 tons) to form a 13-mm diameter pellet, which was then investigated by FTIR using a Thermo Nicolet 380 spectrometer with Omnic software. Single beam spectra ( $4000\text{--}400\text{ cm}^{-1}$ ) were obtained against air as a background, to present the spectra in absorbance units (16–64 scans) under a changing resolution, varying from 8 to  $1\text{ cm}^{-1}$ .

After the infrared spectroscopic examination, the sample-KBr pellet was analysed with a more sensitive chromatographic method. Approximately 500 micrograms of sample was dissolved in 1 mL of dichloromethane, next extracted with 1 mL of  $\text{NaHCO}_3$  and water and centrifuged. The organic phase was dried over anhydrous sodium sulphate and next concentrated over stream of dry nitrogen to volume about 100  $\mu\text{l}$ . The compounds (the fingerprint higher linear n-alkanes and alcohols) of the investigated waxes were identified using a gas chromatograph (GC) coupled to a mass spectrometer Saturn 2000 MS Varian Chrompack with ZB-1 GC (Phenomenex) column ( $30\text{ m}\times 0.25\text{ mm film}\times 0.25\text{ mm ID}$ ). The MS was equipped with an ion-trap analyser set at 1508 for all analyses with an electron multiplier voltage of 1350 V. Scanning ( $1\text{ scan s}^{-1}$ ) was performed in the range of 39–400  $m/z$  using electron impact ionisation at 70 eV. The analyses were carried out using helium as carrier gas at flow rate of  $1.0\text{ mL min}^{-1}$  in a split ratio of 1:20 and the following

programme:  $60\text{ }^\circ\text{C}$  at the beginning and hold 3 min;  $3\text{ }^\circ\text{C/min}$  to  $120\text{ }^\circ\text{C}$  and  $15\text{ }^\circ\text{C/min}$  to  $300\text{ }^\circ\text{C}$ . The injector and detector were held at 200 and  $300\text{ }^\circ\text{C}$ , respectively (Calin-Sanchez et al. 2012). Most of the compounds were identified by retention indices, GC/MS retention indices/authentic chemicals-standards and mass spectra (authentic chemicals and NST05 spectral library collection). The retention index standards used in this study consisted of a mixture of aliphatic hydrocarbons ranging from C-5 through C-27 dissolved in methanol (Szumny et al. 2010).

The X-radiographies of the mould were made on the medical instrument (Quantum Medical Imaging, Quest HF Series) in various conditions. The strength of the current was 400 mA, tube voltage was in a range 65–100 kV and exposure time was very short (10–320 mAs). The object was positioned from 0.05 to 1 m from the X-ray generator.

Two small (3–4 mm long) fragments were cut from the edges of the mould, mounted in the resin (Araldite) ring and polished. The polished surfaces were examined with reflected light petrographic microscope and studied by electron microprobe for major element composition. The choice of analytical points for electron microprobe analyses was done in the BSE (back scattered electron) image, which provided detailed microstructural and compositional information on the studied phases. The beam diameter was set at  $1\text{ }\mu\text{m}$ , which corresponds to the size of the analysed spot.

The CAMECA SX100 electron microprobe at the laboratory of the Department of Lithospheric Research at the University of Vienna, Austria, was used to analyse the major element composition of mould phases. We analysed Ni, Cu, As, Ag, Sn, Sb and Pb as well as the elements which appeared not to occur in the analysed phases: Al, Si, S, Fe and Zn; this choice of elements assures full chemical characterisation of the mould phases in terms of major elements. We used typical conditions for microprobe analyses, with pure metals as standards, except Pb, Sb and As (standards, respectively:  $\text{PbO}$ ,  $\text{InSb}$ , GaAs). The counting times between 20 and 40 s (peak

**Fig. 4** The microphotograph of the inner surface of the mould. In the centre, a *black semi-glossy spot* (beeswax?) is visible

were used, except As, for which the peak counting time was 80 s. This assured the following detection limits (approximate values in ppm): Ni—530, Cu—2000, As—900, Ag—1200, Sn—1400, Sb—2200 and Pb—1450. We used 20 kV acceleration voltage and 10 nA sample current.

The “bulk” metal composition was determined by XRF (Spectro Midex X-ray fluorescence spectrometer with energy dispersion). The spectrometer is equipped with a molybdenum X-ray lamp with excitation energy of 44.6 kV and a Si Drift Detector (SDD) with 150 eV resolution. For calibration, references from Certified Reference Material BCR 691 of the Institute for Reference Materials and Measurements were used. The analysed spot size is ca. 0.7 mm; we analysed Ni, Cu, As, Sn, Sb and Pb plus Fe, Zn and Mn which are below detection limit (the detection limits are Fe–0.003 wt%, Zn–0.004 wt% and Mn–0.002 wt%). The fresh surfaces exposed by cutting samples for electron microprobe were analysed as well as the cleaned surfaces in the other parts of the mould. Most of the analyses (12) yield similar results and were averaged, whereas three are obviously different (Table 1).

### Wax remains

The IR image of wax-like substance shows signatures of mineral substances (Fig. 5), including “bentonite” (clay, used recently mostly in metal casting), chalcocite  $\text{Cu}_2\text{S}$ , chalcocyanite  $\text{Cu}_2\text{S} \cdot 4\text{H}_2\text{O}$ , and chrysocolla  $(\text{Cu}, \text{Al})_2\text{H}_2\text{Si}_2\text{O}_5(\text{OH})_4 \cdot n\text{H}_2\text{O}$  (HR Inorganic, US Geological Survey). Apart from inorganic compounds, bands from the vibrations of hydrocarbons—possibly indicating natural waxes or resins—were identified (Łucejko et al. 2012). These signatures, although very weak, are visible after subtracting the spectra in the following areas: ca. 3000, 1700, 1500–1350 and 700–800  $\text{cm}^{-1}$ . According to macroscopic observations, the material could possibly be the beeswax. The available analyses of archaeological waxes (e.g. Bakr Mossa

et al. 2005; Lattuati-Derieux et al. 2009; IRUG Database. <http://www.irug.org/ed2k/search.asp>) show the beeswax IR-signals at 2955, 2918, 2849, 1462, 1737, 729 and 719  $\text{cm}^{-1}$  (Kovala-Demertzi et al. 2012) and 3428, 2952, 2915, 2844, 1735, 1467, 1375, 1195, 1172, 729 and 721  $\text{cm}^{-1}$  (Luo et al. 2012). Łucejko et al. (2012) argue that wax content is confirmed with a signal of 1460  $\text{cm}^{-1}$ . The analysed specimen gave signals at 3411, 2948–2924–2853, 1733, 1464, 1388, 1165, 730 and 709  $\text{cm}^{-1}$ , corresponding with the identified archaeological samples of beeswax (Fig. 6).

Regert et al. (2001, 2005) show that archaeological beeswax is a mixture of odd-numbered linear hydrocarbons (C21–C33), even-numbered free fatty acids (C22–C30), long chain palmitate esters (C40–C52) and other products of the degradation of the beeswax structure (low molecular weight phenolic compounds, both benzoic and cinnamic acid derivatives), which could be spectroscopically identified.

The hydroxyl group of alcohols is indicated by stretching vibration at 3411  $\text{cm}^{-1}$ ; the next signals in the region of 2950–2850 and 1470–1380  $\text{cm}^{-1}$  confirm the aliphatic compounds (hydrocarbon vibration in fatty acids). Long hydrocarbon chains (also esters) are identified by rocking vibration about 730  $\text{cm}^{-1}$ . The stretching vibrations of saturated esters are identified by peak at 1733  $\text{cm}^{-1}$ .

The GC-MS analysis shows the occurrence of linear saturated hydrocarbons characteristic for beeswax, such as eicosane, docosane, tricosane, tetracosane and hexacosane (Fig. 7). Moreover, free higher linear primary alcohols, such as docosanol or tetracosanol, occur in the studied sample. Because of their chemical stability, non-volatile character and resistance for oxidation process, those compounds are always found in modern beeswax (Maia and Nunes 2013; Regert et al. 2005) materials, as well as in archaeological ones (Lattuati-Derieux et al. 2008).

The small amount of material available for analyses did not allow the full characterisation of the “wax-like” substance.

**Fig. 5** The FTIR spectra of the analysed sample and minerals, identified in the sample

Our data show that it could possibly be the altered remnant of the beeswax.

### The microstructure and chemical composition of the metal

The metal is inhomogeneous, consists mostly of cored dendrites of end composition A and B. The subordinate few tens of micrometres amaeoboidal inclusions of  $\alpha+\delta$  eutectoid in the

dendritic groundmass have the composition C (Fig. 8). The dendrites contain sparse, single micrometre-size droplets of silver, whereas the eutectoid inclusions C contain very small (<1 micrometre) inclusions of bismuth. The size of both silver and bismuth inclusions enabled only qualitative analysis by EDS system.

The microstructure of the metal is variable in terms of size of individual phases; eutectoid is distributed irregularly (Fig. 8). The microstructure appears finer in the frontal (point

**Fig. 6** The FTIR spectrum of the analysed wax sample. The *squares* indicate the beeswax signals

**Fig. 7** Part of GC-MS chromatogram of wax

1 in Fig. 2) part of the mould and coarser in the back (point 2 in Fig. 2) part. BSE images (Fig. 8) reveal also some porosity. The cored dendrites indicate fast cooling of the metal, and the varying arm-spacing of dendrites shows that the rate of cooling was different in different parts of the mould at the time of metal solidification (the coarser dendrites come from the thicker part of the mould which, because of its greater mass, cooled probably slightly slower during casting). The mould preserves the primary (“as-cast”) metal structure, which suggests that it has not been subjected to high-temperature treatment, which would result in metal homogenisation. The mould metal would recrystallize if the mould was used for direct metal casting.

End composition A is mostly copper (96.5–97.9 wt%), containing small amounts of Sn (1.4–2.2 wt.%) and subordinate Sb, As, Ag and Ni (Table 1, analyses 1, 2 and 3, cf. Fig. 9). It marks the onset of dendritic crystallisation, whereas the composition B contains from 84.3 to 87.5 wt% of Cu and ca. 8.9–9.9 wt% of Sn, with significant Sb, As and Ag (Table 1, analyses 4, 5 and 6, cf. Fig. 8) marks its termination. The eutectoid contains ca. 65.4–67.0 wt% Cu and 18.8–

20.0 wt% Sn and is relatively rich in Ni, As and Ag (Table 1, analyses 7, 8, 9, cf. Fig. 8). It is a homogeneous phase in the BSE images, but its composition suggests it to be the  $\alpha+\delta$  eutectoid.

Bulk metal XRF chemical analysis (Table 1, analysis 10) shows “averaged” composition of the metal, which falls in the range defined by two-cored dendrite end compositions A and B. Since most of the analyses yield similar results, we infer that, despite of varying composition of cored dendrites, the relative proportions of dendrite parts and eutectoid forming the mould are approximately constant at the scale of analysed spots. The variation in bulk metal composition (Table 1, analyses 11 and 12) could be attributed to locally different proportion of zones of cored dendrites plus eutectoid.

The obtained X-ray image shows that the state of preservation of the mould is good and the metal core is visible, as well the corrosion layers near the surface. No cracks and splits are recognised; the metal core has some characteristic points, which could be a result of the corrosion process. Inside the mould, the shape of the axe, with characteristic grooves, was recognised (Fig. 10).

**Fig. 8** Back scattered electron (BSE) images of the mould texture; two fragments cut from different parts of the mould exhibit different texture. Composition A of cored dendrites is *dark grey*, composition B is *light grey* and eutectoid C is *white* (see text for details). The *numbers* correspond to the sampling places (cf. Fig. 2)

## Conclusions

The earliest European evidence of beeswax comes from the Neolithic settlement at Ergolding Fischergasse in southern Germany which has been identified as discoloured deposit adhering to the surface of a potsherd (Heron et al. 1994). Another example of early use of wax comes from middle Bronze Age cemeteries from Horta do Folgão and Torre Velha 3 in southwestern Iberia observed as black greasy earth found in three hypogea. As authors demonstrated, the mixture of beeswax and propolis with a clayey earth was used to seal the chambers most likely due to its waterproofing properties (Frade et al. 2014).

Lost wax method has been considered one of the oldest hot metalworking techniques and implied in particular when casting seams are not observed of finished products (Kienlin

2010, p. 42). In the late Bronze Age, lost wax casting was applied in the production of highly elaborate objects and although use of beeswax is undisputable, its remains have never been found in metallurgical context. The waxy remnants in the presented mould do not have to suggest that it was used directly for preparing wax forms, as bronze moulds are rather considered to be designed for axe mass production which excludes use of models (see above and e.g. Drescher 1957). Moreover, the mould was design to cast a rather common type of axe which more likely would be cast directly in the mould instead of preparing a single use model.

The phase and chemical composition data of the Bronze Age casting moulds including both bulk metal and its phase chemical analyses connected with microstructural observations are rare, and the data set we present is, according to our knowledge, the first one in central Europe. Our data show

**Fig. 10** XR image of the mould

that the Gaj Oławski mould metal is dominated by copper, tin and antimony and that it preserved the “as-cast” structure which was not modified by intense reheating, thus was not used for metal casting. Fired organic coatings, mostly charcoal, could have been used as a layer preventing the welding of mould with poured liquid metal, and the wax can represent the remnants of such coating. This would mean that the mould was covered with coating but never fired. Therefore, our data show that the mould, although ready to use, has never been employed in metal casting.
